# Implementation Described

## State Representation

The states in our project are determined by the following attributes:

- x, y position in maze
- number of dots collected thus far
- which dots were collected

In order to optimize performance, we represent which dots have been collected as an unsigned 32-bit integer, where the i-th bit represents whether the i-th dot has been collected or not. We can use bitwise operators to create these numbers quickly.

In order to allow fast lookup of neighbors, we store all maze states visited in a 3D array of hashmaps. The first argument to the array is x-coordinate, the second is y-coordinate, the third is the number of dots collected, and the key to the hashmap is the unsigned integer representing which dots have been collected thus far. This has the benefit of storing **only** the combinations of dots that have been collected thus far, instead of allocating space to account for all  $2^{numberOfDots}$  combinations for every possible position and number of dots collected.

# Frontier Representation

Our frontier is a doubly linked list implemented as a deque, or *double-ended queue*, and synchronized with a min-priority queue. Double-ended means push and pop operations work on both the front and back of the frontier, allowing it to act as a stack or a queue. Moreover, since the frontier is backed by a min-priority queue, the frontier node with the lowest cost can be found and removed in  $O(\lg n)$  time.

It follows that we can use the following functionalities of the frontier for the four different search methods:

- DFS uses frontier as a stack
- BFS uses frontier as a queue
- Greedy uses frontier as a min-priority queue on heuristic cost
- $A^*$  uses frontier as a min-priority queue on heuristic cost + path cost

Figure 17: A\* search on the medium maze

# Our Heuristic, Explained

For our A\* search, we developed a heuristic based on the total weight of a manhattan distance minimum spanning tree that spans the current state position and the dots remaining.

First realize that in graph-theoretic terms, the optimal walk, W, of the maze graph through all remaining dots covers some subgraph S of the maze containing the current state position and each of the remaining dots. It follows that this optimal walk will cost at least as much as the cost of the subgraph it covers, more when edges are traversed multiple times. Letting  $|\cdot|$  denote the cost of its argument, we have

$$|S| \leq |W|$$
.

By definition of a minimum spanning tree, any minimum spanning tree is a minimum cost subgraph of the nodes it contains. Also, notice that by using the manhattan distance function, we are actually underestimating the cost of connecting the dots and the current position in a minimum spanning tree since we don't account the true distance between dots around obstacles. Since S contains at least the same nodes as the minimum spanning tree described, and the minimum spanning tree described (call it MST) is an underestimate of the minimum cost subgraph of these nodes, we can conclude that

$$|MST| \le |S| \le |W|.$$

Therefore, our heuristic is admissible.

#### Minimum Spanning Tree Implementation, Explained

The MSTs are created in  $O(V^2 \lg V)$ , where V is the number of dots remaining in the maze + 1 for the current state position. Since there are often few dots in the mazes, this heuristic can run very quickly. We used disjoint sets in conjunction with Kruskal's algorithm to form the MST.

## Heuristic Efficiency

See that for the small and tiny mazes, we can compare our A\* search to the results of our BFS searches. For both mazes, A\* generates an optimal path through the maze, and moreover, it explores and expands far fewer nodes during the traversal. While we couldn't manage to perform a BFS that would finish on the medium maze, we suspect that our A\* search finds the optimal path for this maze well. It also was able to run rather quickly for the medium maze as well, finishing the search over 90 million nodes in a little over a half hour.

#### Team Involvement

Jon Reynolds was responsible for implementing the maze class, and the node class as well as implementing the minimum spanning tree in section 1.2, as

well as documenting his respective work in the report. Matthew Krikorian was responsible for writing the maze class and the main file which processed the mazes, as well as documenting the respective work in the report. Patrick McMahon was responsible for coming up with the heuristic for section 1.2, as well as implementing the disjoint sets class and the frontier class, as well as documenting his respective work in the report.
